## ABSTRACT

Pollen grains are valuable paleoclimate and paleovegetation proxies which require extensive knowledge of morphotypes and long acquisition time under the microscope. The abundance of damaged, folded, and broken pollen grains in the fossil register and sometimes also in modern soil and sediment samples, has so far prevented automation of pollen identification. Recent improvements in machine learning, however, have allowed reconsidering this approach. Here we present an automated approach which is capable of assisting palynologists with poorly preserved pollen samples. Called multi-CNNs, this approach is based on multiple convolutional neural networks (CNNs) integrated in a decision tree system. To test it, we built a system designed for three botanical families very common in the modern and fossil pollen assemblages of Eastern Africa, namely Amaranthaceae, Poaceae, and Cyperaceae. Our system was tested on stacked optical images of 8 pollen types (6 Amaranthaceae, 1 Poaceae, 1 Cyperaceae) using a training dataset of 1102 intact pollen grains and three validation datasets of intact (276 grains), damaged (223 grains), and fossil pollen (97 grains). We show that our system successfully recognizes intact, damaged, and fossil pollen grains with very low misclassification rates of 0%, 2.8%, and 3.7%, respectively. The use of augmentation on stacked optical images during the training increases classification accuracy. Following a palynologist's approach, our system allows grains without obvious characters to be classified into a class of high taxonomic level or as indeterminable pollen. This is the first software able to process grains with a wide range of taphonomical stages, which makes it the first truly applicable to automated pollen identification of fossil material.

## 1. Introduction

Since the late 1960s, the palynologist community has been interested in the automation of pollen grain recognition (Flenley, 1968). This desire comes from a real need to reduce the long and tedious process of pollen grain identification and counting, which requires an extended knowledge of palynofloras in order to obtain accurate and statistically valid paleovegetation inferences. Pollen counting and recognition process is an important limiting factor that makes it difficult to build large databases. To date, with the advances of large datasets for paleoenvironmental studies to resolve high spatial and/or temporal resolution, there is a crucial need to reduce the time involved in pollen data acquisition. Palynology is also a discipline at risk today because acquiring sufficient knowledge of palynofloras requires years of experience, particularly in tropical regions where plant diversity is highest. Despite the fact that pollen grains are still the only paleovegetation

proxies allowing plant identifications up to the genus and species levels, their study is easily supplemented by other indicators such as  $\delta^{13}\text{C}$ . They require less physical presence of scientists in the acquisition although they do not allow such fine environmental reconstitutions.

In the East African Rift, many paleontological areas have preserved abundant fauna, including hominin remains of Pliocene and Pleistocene age, but few have preserved paleobotanical remains. Yet, pioneering pollen studies in the early 70s have proved to be a powerful tool for inferring paleoenvironments associated with early hominins in Africa (Bonnefille, 1979). Among these, the *Australopithecus afarensis*-bearing Hadar formation in the North Ethiopian Rift was extensively studied, and several levels proved to be rich in pollen grains (Bonnefille, 2010; Bonnefille et al., 1987, 2004). Those levels were analyzed by palynologists of Bonnefille's team, usually over several weeks, in order to obtain adequate pollen counts (generally between 300 and 1000 grains depending on the pollen diversity of each sample) as the depositional

and arid climate contexts were not favorable to pollen preservation (R. Bonnefille, pers. Com.). Recently, the Hominin Sites and Paleolakes Drilling Project (HSPDP) drilled in this area to obtain paleoenvironmental records with high temporal resolution of the variations of the local hominin environment between 2.9 and 3.6 million years (Ma) ago (Cohen et al., 2016). We have been studying two of those HSPDP cores, collected from near the lacustrine depocenter of Hadar Basin, the Northern Awash Osi-Isi (NAO, 11.31518°N, 40.73689°E) and from a location 3 km east of NAO, the Northern Awash Woranso (NAW, 11.32535°N, 40.76491°E). NAO and NAW were cored respectively to a depth of 187 and 245 m below surface (Mohan et al., 2016). Analysis of 8 samples out of 175 from these two cores took one of the authors (B.B.) several months to complete, because both the preservation and concentration of pollen grains were low. A high-resolution pollen record at this site would give a fantastic record of paleovegetation changes during the time when *Australopithecus afarensis* thrived and when the first representatives of the *Homo* genus emerged (Maslin et al., 2015; Villmoare et al., 2015), but such a study would require more than one scientist working full time over several months. It is a classic case of “arid” sedimentary archives with very important environmental pollen data that cannot be correctly studied due to human limitations. Testing and exploring the potential of automated recognition to pollen taxa is, therefore, crucial.

In the 1960s, computer performance, image processing, and machine learning techniques were not sufficiently developed to realize Flenley (1968)'s visionary concepts of pollen recognition. During the last decade, however, dramatic improvements opened the way to automated recognition of pollen, through different approaches such as (1) feature extraction, (2) texture analysis, and (3) the combination of both. (1) Regarding feature extraction, the first breakthrough study by García et al. (2012) combined morphological methods based on contour feature extraction of light microscopy (LM) images with a hidden Markov model (HMM) classifier. This approach allowed classifying 17 different pollen types from 11 different botanical families of honey bee's plants with 98.8% accuracy. Kaya et al. (2013) used morphological measurements (polar axis length, equatorial axis length, colpus weight, exine thickness, etc.) with a data mining classifier to predict group membership for data instances. This approach allowed 20 very similar species of pollen grains in the genus *Onopordum* to be classified with an accuracy of 90.6%. The work is impressive but requires an initial manual/subjective definition of the recognition characteristic features and is only applicable to intact pollen grains. In addition, the accuracy of Kaya et al. (2013)'s model is dependent of the choice of characteristic features (Treloar et al., 2004).

(2) Another set of studies focused on texture analysis, with texture features derived from gray level patterns of the grain surface (Fernandez-Delgado et al., 2003). Using a combination of local linear transformation (LLT) feature vectors and a support vector machine (SVM) classifier, Fernandez-Delgado et al. (2003) were able to classify LM images of fresh pollen of five pollen types (in four different families) with an accuracy of 76%. Later, a more complex approach was developed by Marcos et al. (2015) using a texture feature vector composed of gray-level co-occurrence matrices (GLCM), log-Gabor filters (LGF), local binary patterns (LBP) and discrete Tchebichef moments (DTM), and Fisher's discriminant analysis (FDA) and k-nearest neighbor (KNN) to reach a final classification at the family level. This study achieved an accuracy of 94.8% for LM images of fresh pollen grains of 15 pollen types in 12 families (Marcos et al., 2015), but the texture approach has been shown to be sensitive to grain rotation, lighting, image noise and the quality of texture preservation (Han and Xie, 2018). To circumvent these problems, Han and Xie (2018) proposed to use local decimal patterns (LDP) instead of LBP, an approach robust to the noise and rotation of pollen images but which, nevertheless, could not tackle the challenge of recognizing damaged pollen.

(3) A combination of texture features and morphological analyses represents the last development. Rodríguez-Damian et al. (2006) developed a classification system using both shape and texture analysis

of LM images of pollen grains directly extracted from plants. Using a minimum distance classifier (MDC), multilayer perceptron (MLP) and SVM, three morphologically similar pollen types of Urticaceae were classified with an accuracy of 89%. Later, Chudyket al. (2015) used a combination of 15 morphological features and five textures features on a set of LM images including one pollen type of Poaceae, one of Asteroideae and three of Betulaceae. By using SVM and Random Forest classifiers, they reached a success rate of 89% for intact pollen grains. However, this approach still performed poorly on damaged pollen.

Recently, the development of convolutional neural networks (CNNs) has opened a new era in image recognition. CNNs automatically extract the features of interest in an image that are relevant to the classification task (Daood, 2018). With this approach, intact pollen grains were identified with an accuracy of 97.2% with a LM images dataset (Gonçalves et al., 2016). CNNs with different topology were also tested and allowed classifying 23 pollen types with large morphological differences (Sevillano and Aznarte, 2018). Daood et al. (2018) recognized z-stacked LM images of intact pollen by combining CNN feature vectors with recurrent neural networks (RNN). They achieved an accuracy of 100% for the classification of 10 pollen types of different families. Comparisons of these methods and their success rates on the same data set of images showed that the approaches based on CNNs are always the most accurate, and point toward the efficiency of CNNs in classifying natural objects such as pollen.

All these approaches proved to be efficient only on modern and generally intact pollen grains, far from the reality faced by palynologists who must deal with damaged pollen due to taphonomic processes. Holt et al. (2011), Holt and Bennett (2014) and recently Khanzhina et al. (2018) noticed the absence of a system adapted to “broken, deformed and clumped pollen” and explained it by technological limitations. Han and Xie (2018) pioneered the analysis on damaged pollen grains, unfortunately their approach did not succeed. Punyasena et al. (2012), however, successfully classified fossil grains of two *Picea* species (*P. mariana* and *P. glauca*) with an accuracy of 93.8%. They used a KNN with layered learning systems based on kernel density, applied to extracted shape and texture features from 3D fluorescence microscope (FM) images. Using the same set of pollen grains as Punyasena et al. (2012), Kong et al. (2016) also obtained a high accuracy of 86.1% in classifying fossil grains of three *Picea* species (*P. mariana*, *P. glauca* and *P. critchfieldii*) using dictionary learning sparse coding (DLSC) on shape and texture features extracted from confocal FM images. However, the performances were largely dependent on the selection and quality of sample blocks (Kong et al., 2016; Han and Xie, 2018). These results are nonetheless very promising, but we note that the deterioration of the *Picea* pollen considered in those two studies is very subtle (as is generally observed in peat sediments, e.g. Curry, 2007), and far from resembling the Pliocene pollen records of Eastern Africa.

The aim of this study is to develop a new system of automated identification of pollen that could be applied to down core fossil pollen grains. This system should be able to handle damaged and broken pollen grains, and should be easily applicable to images obtained with light microscopy (LM), as is commonly done in palynological laboratories. It should also allow identifications at higher taxonomical levels when identification at the species level is not reached.

Following recent developments in machine learning we chose to develop our system using sequential multiple CNNs. As a proof of concept for this study we chose eight pollen types: six among the Amaranthaceae, as they have very similar overall shape (spherical, periporate), one Poaceae (undifferentiated taxa), and one Cyperaceae (undifferentiated taxa), that is two Monocotyledonae with heterogeneous and varying surface patterns (psilate to finely verrucate). We focused on Amaranthaceae, Poaceae, and Cyperaceae because these three families represent 50%–90% of the total pollen assemblage in both terrestrial and marine archives from Eastern Africa (Bonnefille et al., 1987; Bonnefille, 2010). Pollen-based biome reconstruction for Africa also largely rely on the presence and relative abundance of

Amaranthaceae pollen (Sobol and Finkelstein, 2018). Amaranthaceae species, despite exhibiting very similar pollen morphologies are important ecological markers ('African Plant Database', 2019). Being able to identify and count separately different Amaranthaceae could definitely improve paleoenvironment inferences. As a first step, this study makes no attempts to separate types among Poaceae and

Cyperaceae, also because such discriminations have only been achieved so far using Scanning Electron Microscopy (Mander et al., 2014).

**Fig. 1.** Pollen images with automatic z-stack of  $128 \times 128$  pixels for all pollen types of the intact, damaged, and fossil pollen datasets. The name under each image is the final label assigned by the multiple convolutional neural networks (multi-CNNs) with augmentation.

## 2. Material and methods

### 2.1. Datasets and image acquisition

We prepared one training and three validation datasets by taking pictures of pollen grains under light microscopy (LM) (Supporting Information, Table S1). The training dataset consists of 1102 globally intact pollen grains (hereafter referred to as the training dataset). The three validation datasets consist of 1) 276 grains of intact pollen (hereafter referred to as the intact dataset), 2) 223 deformed, folded, fragmented and/or broken grains (hereafter referred to as the damaged dataset), and 3) 97 pollen grains from Holocene and Pliocene age (hereafter referred to as the fossil dataset) (Fig. 1). In the fossil dataset, pollen grains also have an altered exine and mineral inclusions (Fig. 1). Using specimens from the reference collection of East African pollen species hosted at CEREGE, Aix-en-Provence, France (Supporting Information, Table S1), eight pollen types were imaged to constitute the training dataset, the intact dataset, and the damaged datasets. These types are *Achyranthes*-type *aspera*, *Aerva*-type *javanica*, *Aerva*-type *lanata*, *Celosia*-type *argentea*, *Cyathula*-type *orthacantha*, *Digera*-type *muricata*, Poaceae, and Cyperaceae. The fossil pollen dataset includes only five of the eight pollen types available in the reference collection due to the limited availability of fossil material. These types are *Achyranthes*-type *aspera*, *Aerva*-type *javanica*, *Digera*-type *muricata*, Cyperaceae, and Poaceae (for sampling locations, depth, and ages see Supporting Information, Table S1). The damaged and fossil datasets were built using samples which were not considered for the training and intact pollen datasets to avoid biases in the estimation of the effectiveness of our approach.

Each pollen grain was imaged under natural light by taking a stack of pictures at 1  $\mu\text{m}$  steps between the top and bottom surfaces of the grain, using an automated custom Leica DMRBE microscope controlled with a software. This step is semi-automated, whereby the image stack movement (z-axis) is automatic but setting the position (x and y axes) is performed manually. Since the stacking step is fixed to 1  $\mu\text{m}$ , the number of fused images is proportional to the size of the pollen. The number of images in the stack ranged from 20 to 40 depending on pollen type. Each stack was split into two halves, and only the half corresponding to the top hemisphere of each pollen grain was kept. The image stack was fused to create a single in-focus image (z-stacked imaging process) with the Helicon Focus 6 software, using the “depth map” method with radius set to 50 pixels and smoothing set to 10 pixels. We chose 1  $\mu\text{m}$  steps empirically, as above this threshold the morphological information was less visible in the fused images and below this value, aberrations appeared into fused images. Each fused image was analyzed using a custom script written for the Fiji image analysis software, to center and crop the pollen into a square image (Schindelin et al., 2012). Finally, all reframed fused images were resized to 128  $\times$  128 pixels.

### 2.2. Image classification

Our system of automatic recognition is developed in the Python language (Pérez et al., 2011) and principally uses the Keras and TensorFlow open-source software libraries (Abadi et al., 2016; Chollet, 2015). It uses convolutional neural networks (CNNs) with a linear architecture similar to VGGNet (Simonyan and Zisserman, 2014). The CNN training was done with the training pollen dataset and the validation dataset with intact pollen. CNNs training was carried out on batches of 101 pictures (out of a grand total of 1102 pictures) over 500 epochs (the learning algorithm is an iterative process; an epoch is one training iteration on all pictures). To optimize the convergent behavior in loss function, which ensures a more precise adjustment of the weights of our network, we used regressive learning rate as a function of the epoch such as epoch [0; 200] = 0.001, epoch [201; 300] = 0.0006, epoch [301; 400] = 0.00036, and epoch [401; 500] = 0.000216.

We added an augmentation procedure to most of our trainings to

generate new images at each epoch. This procedure generates new images by modifying the originals through random rotations (0°–90°), random horizontal and vertical flips, and random width and height shifts (0%–25%). But learning often did not progress when using augmentation because the generation of new images at each epoch made it difficult for the CNN to extract features. To solve this problem, we pre-trained the CNN without augmentation to extract features in its initial layers, then continued training using augmented images. By using this pretrained network for the training with augmentation, the CNN learns to combine these features at the end of the initial layers. This process is commonly called transfer learning (Daood, 2018) (Supporting Information, Fig. S1).

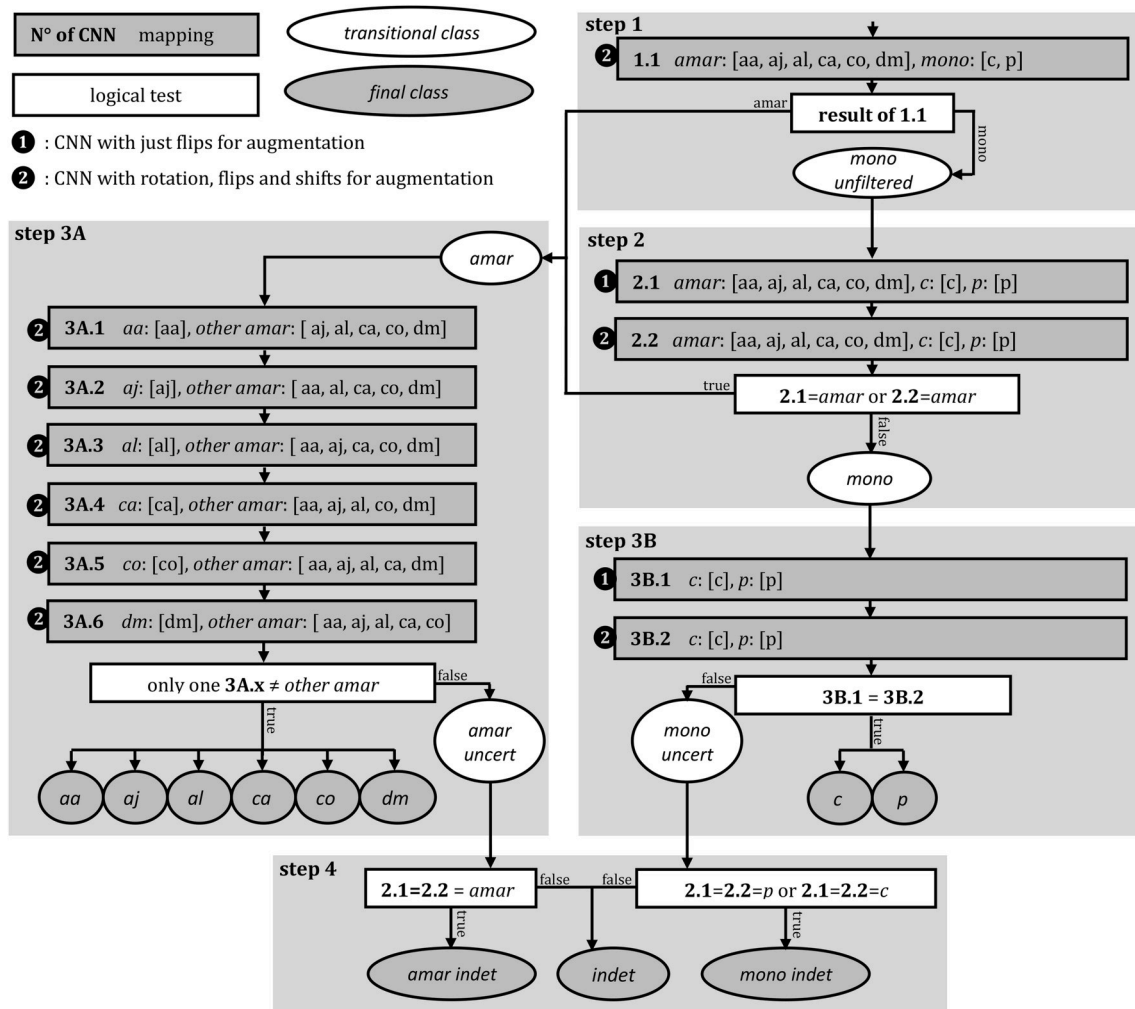

The CNNs trained with augmentation are integrated in a decision tree to form a multiple convolutional neural network (multi-CNNs) (Fig. 2). The multi-CNNs is composed of five main steps. Step 1 aims at isolating *Amaranthaceae* from *Monocotyledoneae*. Step 2 evaluates if pollen identified as *Monocotyledoneae* in step 1 could be altered *Amaranthaceae*. Indeed, altered pollen of *Dicotyledoneae* which have lost their ornamentations and part or all their outer layer (ectexine) may show similarities with *Monocotyledoneae* that only have one layer of exine. To do this in step 2, we used a finer mapping with a separation of Poaceae and Cyperaceae which exhibit different morphologies when intact or slightly altered. Altered *Monocotyledoneae* such as Poaceae and Cyperaceae may easily lose parts of their exine and be deformed or broken, because they are made of a single thin layer. To optimize the chances of recognition of altered pollen, two networks with the same mapping were used but with different augmentation, one focused on shape (CNN 2.1), and the other one on texture (CNN 2.2). In step 3A, several CNNs were used; each one being specialized in the recognition of one pollen type of *Amaranthaceae* to maintain CNN high accuracy. The results of all these specialized CNNs are then compiled, the pollen is classified into one *Amaranthaceae* pollen type or as *Amaranthaceae* uncertain. In step 3B, the same logic is used as for step 2: two networks with the same mapping are used with different augmentation to separate Poaceae and Cyperaceae. If the results of the two CNNs are incongruous, the pollen is classified as an uncertain *Monocotyledoneae*. Finally, in step 4, we use the results of the CNNs 2.1 and 2.2 to classify *Monocotyledoneae* uncertain and *Amaranthaceae* uncertain in *Monocotyledoneae* indeterminate, *Amaranthaceae* indeterminate, or indeterminate pollen.

To evaluate the efficiency of augmentation and multi-CNNs, we tested three other approaches: (i) one using multi-CNNs without augmentation in step 1 and 3A, (ii) one simple-CNN without augmentation, and (iii) another simple-CNN with full augmentation of random rotation of 0–90°, random horizontal and vertical flip, and random width and height shift of 0–25%. The number of palynomorphs analyzed for each pollen type in the intact, damaged, and fossil sets is unbalanced. The number of fossil grains for each type, in particular, is low. As such, we used the average per-class accuracy (APC%) as it is more appropriate for the evaluation of the algorithm performance in this case (Zheng, 2015).

## 3. Results

### 3.1. Global comparison of used/unused augmentation and single-CNNs/multi-CNNs

The four different classification setups yield misclassification rates of 0%–5.9% for intact pollen, 2.8%–22.5% for damaged pollen, and 3.7%–45.3% for the fossil pollen. The multi-CNNs including augmentation always gives the best results (Fig. 3). Compared with the three other setups, the one using augmentation and multi-CNNs increases the success rate for classification in the lowest taxonomic levels (*Achyranthes*-type *aspera*, *Aerva*-type *javanica*, *Aerva*-type *lanata*, *Celosia*-type *argentea*, *Cyathula*-type *orthacantha*, *Digera*-type *muricata*, Poaceae, and Cyperaceae) and keeps classification rates at 99.3% for intact pollen, 85.7%

**Fig. 2.** Schematic of the classification system based on multiple convolutional neural networks (multi-CNNs) with augmentation. aa: *Achyranthes*-type *aspera*; aj: *Aerva*-type *javanica*; al: *Aerva*-type *lanata*; amar: *Amaranthaceae*; c: *Cyperaceae*; ca: *Celosia*-type *argentea*; co: *Cyathula*-type *orthacantha*; dm: *Digera*-type *muricata*; mono: *Monocotyledonae*; p: *Poaceae*; uncert: uncertain; indet: indeterminate.

for damaged pollen, and 80.8% for fossils pollen (Fig. 3).

In detail, augmentation increases the success rate for classification in lowest levels for simple-CNN and multi-CNNs by +3.1% and +2.7% for intact pollen, +3.1% and +16.3% for damaged pollen, and +10.5% and +43.8% for fossil pollen, respectively. Image augmentation also reduces misclassification rates for simple-CNN and multi-CNNs by −3.1% and −0.8% for intact pollen, −3.1% and −7.3% for damaged, and −10.5% and −12.6% for fossil pollen, respectively (Fig. 3). Similarly, the use of multi-CNNs reduces misclassification rates, for the scripts without augmentation (−5.1% for intact pollen, −12.4% for damaged, and −29% for fossil pollen), and for those with augmentation (−2.8% for intact pollen, −16.6% for damaged, and −31.1% for fossil pollen) (Fig. 3).

Multi-CNNs with augmentation also increase the detection of *Amaranthaceae* and *Monocotyledonae* misclassification in step 1 and 2. For the damaged dataset, five misclassified pollen grains of *Monocotyledonae* were directed into step 3A normally reserved to *Amaranthaceae* (Supporting Information, Fig. S2a). All of these five misclassified pollen grains of *Monocotyledonae* were identified as *Amaranthaceae* uncertain in step 3A (Supporting Information, Fig. S2a) then classified as pollen indeterminate in final step 4 (Fig. 2). This is also observed for fossil data in Step 3A and Step 3B (Supporting Information, Figs. S2c and d).

### 3.2. Details of efficiency of Multi-CNNs with augmentation

Our Multi-CNNs with augmentation classified the intact pollen grains with misclassification rates of 0%. All intact pollen are correctly classified (Fig. 3). We show that within the *Amaranthaceae* family, six types with similar morphologies can be distinguished. Over 208 images of intact *Amaranthaceae* pollen, 99.3% were successfully classified within different *Amaranthaceae* types and only 0.7% (two *Cyathula*-type *orthacantha*) could not be clearly identified but could still be defined as *Amaranthaceae* indeterminate (Figs. 3 and 4a). For *Poaceae* and *Cyperaceae*, all were correctly classified as *Poaceae* and *Cyperaceae* despite the heterogeneity of textures and features, and the complex shape of *Cyperaceae* grains.

The damaged pollen grains, however, show a higher misclassification rate than intact pollen with 2.8% misclassification (Fig. 3). Like for intact pollen, the misclassifications are evenly distributed to different classes (Fig. 4b). 85.7% of the damaged pollen have been successfully classified to the lowest taxonomic levels (*Achyranthes*-type *aspera*, *Aerva*-type *javanica*, *Aerva*-type *lanata*, *Celosia*-type *argentea*, *Cyathula*-type *orthacantha* and *Digera*-type *muricata*, and *Poaceae* and *Cyperaceae*) and 6.6% have been successfully classified to higher taxonomic ranks (5.6% in *Amaranthaceae* indeterminate, and 1% in *Monocotyledonae* indeterminate), that is −13.6% and +5.9% than intact pollen, respectively. Of the 167 pollen classified as *Amaranthaceae*, only 6.6% were classified as *Amaranthaceae* indeterminate, 6.6% were classified as pollen

**Fig. 3.** Results of our classification system (multi-CNNs with augmentation) as a function of pollen dataset and in comparison with other setups. Pollen types of the lowest taxonomic levels: *Achyranthes*-type *aspera*, *Aerva*-type *javanica*, *Aerva*-type *lanata*, *Celosia*-type *argentea*, *Cyathula*-type *orthacantha* and *Digera*-type *muricata*, and Poaceae and Cyperaceae. indet.: indeterminate. The APC% is the percentages based on average per-class.

indeterminate, and none were misclassified as Monocotyledonae indeterminate (Figs. 3 and 4b).

The fossil grains were classified with 3.7% misclassification, a +0.9% increase compared to damaged pollen (Fig. 3). In this case, misclassifications are also evenly distributed into different classes (Fig. 4c). 80.8% of total pollen are successfully classified to the lowest taxonomic levels, compared to −4.9% for damaged pollen. We have one increase of pollen classified to higher taxonomic ranks (+4.8%) compared with damaged pollen. We also show a slight decline of pollen classified as pollen indeterminate with a rate of 4% (Fig. 3). The presence of mineral inclusions does not seem to interfere with identification (Fig. 1). Finally, out of the 30 pollen classified as Amaranthaceae, 17% were classified as Amaranthaceae indeterminate.

#### 4. Discussion

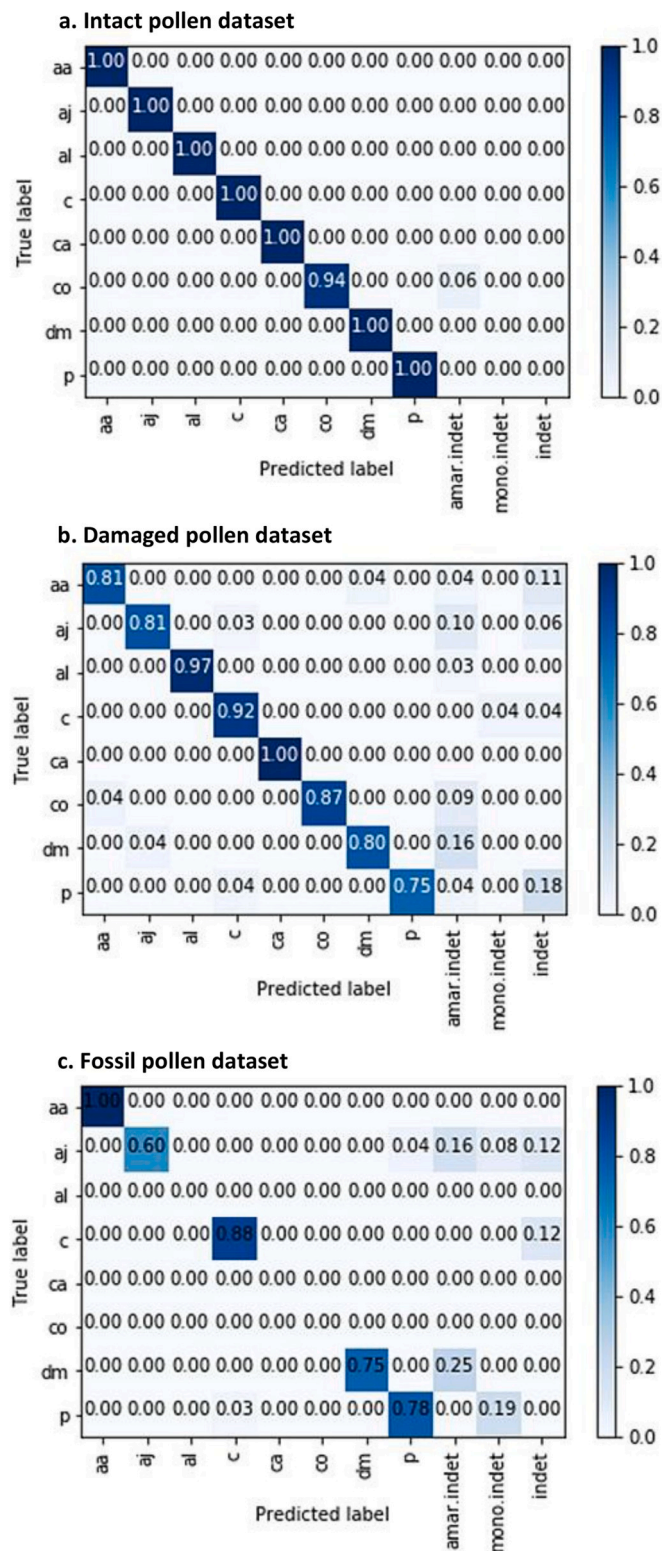

Our model has been tested on several datasets with success. The overall computing time required to setup automatic recognition (time required to do all trainings) was about 11 h using the Nvidia Titan XGPU for the computing. After the training, each test (inference) takes less than a minute on the same machine, and reproducibility tests show slight variations of <2 APC% (not shown). Our study uses image datasets for the “training dataset”, “intact dataset”, and “damaged dataset” which sizes are in the range of the automatic recognition studies mentioned above, but some may argue that our “fossil dataset” is relatively small. It is, however, a good test for our model because the proportions of Amaranthaceae, Cyperaceae, and Poaceae pollen in the fossil image dataset are close to proportions that are usually observed in modern and fossil pollen assemblages of about 300–400 grains from arid areas of northeastern Africa. The results on the fossil data give a good overview of what can be obtained on real fossil samples. One caveat, not addressed in our study, is that usually, not all pollen types in the fossil/modern sediment or aerial trap are known. As such, the future automatic recognition systems will have to include in the training dataset pollen types that are not related to any of the analyzed/tested types. We are

confident, however, that our system should perform well because in our experiment on the fossil pollen dataset, which had none *Aerva*-type *lanata*, *Celosia*-type *argentea*, and *Cyathula*-type *orthacantha*, we reached significant levels, suggesting that including unknown pollen types should not be a major problem in future applications.

Our study shows that a single CNN is not able to manage the recognition of 8 pollen types when the dataset includes damaged or fossil pollen. With a single CNN, misclassification considerably increases with increased grain deterioration. The origin of this problem is linked to the attempt to classify into low taxonomic ranks highly degraded pollen which have lost most of their surface features and ornamentation. This loss of information complicates the recognition by the CNN when the CNN has been trained to recognize eight pollen types. The new approach we designed and which combines the use of augmentation and multi-CNNs, increases the accuracy of classification for the damaged and fossil pollen. This is principally related to the reclassification of highly degraded pollen into higher taxonomic ranks, and the use of CNNs with augmentation and specialized in the recognition of only one pollen type at a time for the lower taxonomic ranks. The multi-CNNs system is also useful for identifying and self-correcting a significant part of these misclassifications at the high taxonomic level in steps 1 and 2, with the support for the systems set up in steps 3A and 3B. The need for this self-correction is negligible for intact pollen due to the absence of misclassification at the high taxonomic level, but is important for the damaged and fossil pollen which do have misclassification at the high level due to their deteriorated features. Consequently, it is very relevant to use augmentation and a multi-CNNs system for the recognition of fossil or damaged pollen grains.

Our approach based on multi-CNNs with augmentation classifies each class of intact pollen with 0 APC% error. This is as good as in recent studies on intact pollen with a similar number of pollen types (Khanz-hina et al., 2018; Sevillano and Aznarte, 2018; Daood, 2018; Daood et al., 2018). For the damaged pollen, we achieved misclassification rate of 2.7 ACP%, which is slightly higher than that of intact pollen (Fig. 1). To our knowledge, this is the first time that such good accuracy on

**Fig. 4.** Confusion matrix for the intact (a), damaged (b) and fossil (c) pollen dataset for final classes. aa: *Achyranthes-type aspera*; aj: *Aerva-type javanica*; al: *Aerva-type lanata*; amar: *Amaranthaceae*; c: *Cyperaceae*; ca: *Celosia argentea*; co: *Cyathula-type orthacantha*; dm: *Digera-type muricata*; mono: *Monocotyledonae*; p: *Poaceae*; indet: indeterminate.

highly damaged pollen grains has been reached (Holt and Bennett, 2014; Han and Xie, 2018; Khanzhina et al., 2018). Based on all human-made pollen counts of actual soil and mud samples in the African Pollen Database available for Ethiopia (115 samples), we find that indeterminate (i.e. damaged) pollen represent on average about 8% of total pollen count, and that indeterminate *Amaranthaceae* are most common: they represent about 35% out of total *Amaranthaceae* ('African Pollen Database', 2019). Our percent of indeterminate pollen out of the total pollen (2.7 APC%) and of indeterminate *Amaranthaceae* out of the total *Amaranthaceae* (5.6 APC%) are thus better than the human counts, for modern damaged pollen in the Ethiopian dataset (Bonnefille, 1972; Buchet, 1982; Abadi et al., 2016).

As mentioned before, Punyasena et al. (2012) and Kong et al. (2016) obtained good results for fossil pollen of *Picea*, but the grains in their study came from a peat; altered pollen in peat cores are far from resembling altered fossil pollen grains from lacustrine Pliocene samples. Our approach is the first to present successful results (only 4.1% misclassification) for fossil pollen with important deterioration, typical for arid areas. In the human-made Pliocene pollen dataset of about 25 samples obtained for the Hadar formation by Bonnefille's team (Bonnefille et al., 1987) indeterminate pollen may account for up to about 30% of total pollen counts (10% in average). Of these 25 samples, 19 have *Amaranthaceae* of which about 80% on average were classified as "*Amaranthaceae* indeterminate" (Bonnefille et al., 1987). The percentage of fossil pollen indeterminate that we obtained with our automated system is of 4%, i.e. well within the average of Bonnefille et al. (1987), and the taxonomic precision is better as only 17% of *Amaranthaceae* were classified as indeterminate. Our method, therefore, has the potential to be applied to both damaged, fossil, and modern pollen grains from arid areas, and may even improve pollen taxa identifications within the *Amaranthaceae*.

Using our multi-CNNs with augmentation, we were able to classify both morphologically similar pollen (pollen types of *Amaranthaceae*) at the species or genus level, and morphologically different pollen (*Amaranthaceae* versus *Poaceae* versus *Cyperaceae*), without having significant misclassification for intact, damaged, and fossil pollen (Fig. 4). For the *Monocotyledonae*, we can observe an increase in fossil pollen classified as indeterminate *Monocotyledonae* (+6.8%) in comparison to the damaged pollen, but we do not have significant increases for *Amaranthaceae* (Fig. 3). The fossil grains of *Monocotyledonae* have more mineral inclusions than *Amaranthaceae*, but we discard the hypothesis that mineral inclusions in pollen is the origin of these increases because fossil pollen of *Monocotyledonae* bearing mineral inclusions are correctly identified (Fig. 1). We see on the images that fossil pollen of *Monocotyledonae* is often "stuck" in residual sediments (Fig. 1). This is very similar to images of "contaminated grains" of Han and Xie (2018), who suggested that this hinders identification. Our study shows that our system overcomes the sediment contamination and is able to correctly identify fossil pollen of *Amaranthaceae* even when sediment is attached to the grains. The deformation of pollen grains is another hindrance to identification (Holt et al., 2011; Han and Xie, 2018; Khanzhina et al., 2018) but our fossil grains of *Monocotyledonae* are no more deformed than damaged grains of *Monocotyledonae* or fossil grains of *Amaranthaceae* (Fig. 1). We posit that, within the biodiversity range we investigated, this issue stems from the structural weakness of *Monocotyledonae* (in the pollen studied) as this family shows a thinner and weaker exine than *Amaranthaceae*. As for human eyes, automated pollen recognition requires that the exine texture must be relatively well preserved. This agrees with the idea of Li et al. (2004) that the "surface texture is frequently characteristic, even when grains are damaged or fragmented" for the pollen.

Our multi-CNNs with augmentation is operational. At CEREGE, it is used occasionally to assist with identification of fossil *Amaranthaceae* when identification to type is not straightforward. The main bottleneck to an extended use of our recognition system is the acquisition time, which is manual and therefore, time-consuming, preventing an easy

addition of new pollen types. Adding an automated acquisition step would therefore provide a complete automatic pollen counting system, saving a lot of time for palynologists of arid areas and possibly elsewhere. With such a system, it would probably be easy to acquire images of large pollen reference collections within in a few months. The prospect of a fully automated pollen counting system for paleoclimatic and paleoenvironmental reconstructions, similar to the operating systems developed for other microfossils like coccoliths or foraminifera (Beaufort and Dollfus, 2004; Marchant et al., in preparation), can be foreseen in the very near future. These automated systems will pave the way to high-throughput palynology studies, including morphometric studies.

## 5. Conclusions

In this study, we proposed a robust system for classification of very damaged and badly preserved fossil grains. We have developed a classification topology that has flexibility in the choice of taxonomic levels used for classification. It can, like a palynologist, assign higher taxonomic ranks if the characteristics of the image are not sufficient for robust identification at a lower taxonomic level. Moreover, if images cannot be properly classified, it can declare them as indeterminable. Our system has the advantage of using simple LM images and does not require the implementation of complex and expensive systems such as confocal fluorescence microscopes. With the damaged pollen, we have obtained results similar to or better than those obtained from human pollen counting performed by CEREGE palynologists on modern soils and Pliocene sediments of the Awash Valley in Ethiopia.

The system developed here does not yet allow a complete count of fossil pollen. It remains limited to a few families and to a very limited number of taxa in comparison to overall pollen diversity. Evaluating and improving how the system reacts to pollen types or other grains not included in the training set is also important because usually not all pollen types in the sediment core are known. To handle this, one solution may be the addition of an “unknown” category. Our results, based on a limited dataset but representing a wide range of biases affecting pollen grains from their production to their fossilization, allow the possible development of automatic pollen recognition for routine palynological studies of samples coming from multiple depositional environments and with different degrees of pollen alteration. It would also be interesting to see if it is possible to increase the accuracy of our system with the use of a much larger number of training images.

It is also important to specify that the system presented here cannot be directly extended to other pollen families as it relies more on the morphology of the pollen types than on the taxonomic relationship, although the two are related. It is also important to have a good knowledge of how the morphology of each type of pollen changes with degradation or fossilization in order to build relevant mappings and logical steps in the classification system to cover all stages of pollen grain degradation. The expertise of paleo-palynology is therefore critical to the extension of this system.

The next step of this work will be to extend the system to automatically take pictures of pollen grains from microscope slides. The automatic acquisition will be inspired by the processing software developed for coccoliths at CEREGE (Beaufort and Dollfus, 2004) and modified by Martin Tetard and Yves Gally for Radiolaria tests (Martin Tetard, personal communication). It can be summarized in 6 steps: (1) color pollen grains with safranin for easier segmentation, (2) take grayscale images of microscope fields of view (FOVs) by incrementally stepping through the slide (1  $\mu\text{m}$  step), (3) segment each pollen grains in each stacked FOV (saving their x and y coordinates on the original unstacked FOV), (4) generate sub-stacks for each previously recorded pollen grain from each original unstacked FOV, (5) remove the unfocused pollen images from each pollen sub-stack using a gray level threshold, and (6) apply the method in the second paragraph of part 2.1 for finalizing image processing prior to automated recognition. With this automatic acquisition, it will be possible to fully scan reference pollen collections and thus

quickly build a large database of pollen images to develop an automatic pollen counting system (acquisition and recognition) for modern and fossil pollen from eastern Africa, for example.

## 6. Computer code availability

All files and folders presented here are downloadable at <https://github.com/Beniofh/Multi-CNN>. We used the script `Multi-CNN_test_V3.5.2.py` (40.9 Ko) to recognize pollen types using multi-CNNs with augmentation. Multi-CNNs with augmentation is compared to single-CNN with augmentation (script `CNN_test_v2.1.0.py`, 16.5 Ko), single-CNN without augmentation (`CNN_test_v2.1.0 (without_aug).py`, 16.5 Ko), and multi-CNNs without augmentation (`Multi-CNN_test_V3.5.2 (without_aug).py`, 40.9 Ko). In the CNN solo folder, we have for each CNN model parameters, a folder with file of CNN model parameter used in .ckpt, histograms of accuracy, loss and learning rate during the training in .bmp and table of accuracy, loss and learning rate during the training in .csv formats. The folders “intact”, “damaged” and “fossil” contain respectively the images for “training dataset”/“intact pollen dataset”, “damaged dataset”, and “fossil dataset”. The `User_manual.pdf` explains how to use these scripts to reproduce our results.

These scripts have been developed by Benjamin BOUREL ([benjaminbourel1@gmail.com](mailto:benjaminbourel1@gmail.com); +33 6 63 49 85 24) with the help of Ross MARCHANT. These scripts were first available the 13<sup>th</sup> October 2019. They were created in the open-source Anaconda 3 v.5.2.0 (<https://www.anaconda.com>) with Spyder v.3.3.6 in python v.3.6 (Pérez et al., 2011). We also used NumPy (Oliphant, 2006), Scikit-image (van der Walt et al., 2006), Scikit-learn (Pedregosa et al., 2011), and Matplotlib (Hunter, 2007) packages. The details of the python libraries used (name and version) are indicated in `User_manual.pdf`. All software and python libraries used here are open sources. For optimal use, please use the indicated versions.

## Authorship statement

BB, DB, TdG and LB planned the research. BB designed the research and acquired data. RM, MT and BB wrote the script for automated recognition by convolutional neural networks. DB supervised data selection. LB and YG supervised data acquisition with automated microscope. TdG supervised calibration of automated recognition. BB, RM, MT, TdG and DB wrote the manuscript.

## Acknowledgments

We thank J-C. Mazur of the CEREGE's micropaleontology platform for help during pollen sample preparations, and F. Chalié for the automated microscope. We also thank G. Gassier for help with the server, and M. Djamali for his pollen slides from Urima Lake (Iran). This work was supported by Aix-Marseille University (doctoral fellowship to BB), the research grant ANR PRCE FIRST ANR-15-CE04-0006-01. The research leading to these results has received funding from the People Program (Marie Curie Actions) of the European Union's Seventh Framework Program (FP7/2007–2013) under REA grant agreement n. PCOFUND-GA-2013-609102, through the PRESTIGE program coordinated by Campus France.
